EFFECT OF CARCASS SUSPENSION METHOD ON WATER HOLDING CAPACITY OF
M. LONGISSimus FROM FALLOW DEER (DAMA DAMA) AND LAMB

Background
Quality assurance of deer meat (venison) is essential to long-term product marketability and has been
identified as a key challenge for the Australian deer industry. Consumer attitudes and preferences are
increasingly important for all meat industries, and pasture based production systems (as used for deer and
lamb) are often valued by consumers as more animal friendly and ethical compared with the intensive
production of beef in feed-lots, pork and chicken. Technological meat quality attributes like pH and water
holding capacity are related to the functional properties of meat during storage and processing. These quality
parameters also have an indirect influence on the sensory quality of meat, such as tenderness, juiciness and
flavour, valued by consumers as the most important in relation to the eating quality of meat.

Technics for hanging carcasses (Achilles tendon suspension and pelvic suspension) have been studied for
beef (Hostetler et al., 1970; Lundesjö Ahnström et al., 2003) where the variation in tenderness is considered
to be the main reason for consumer dissatisfaction (Koohmaraie, 1996). The tenderness in meat from bulls
was more improved as an effect of pelvic suspension compared with meat from heifers (Fisher, 1994;
Lundesjö Ahnström et al., 2003). Similar results have also been reported for fallow deer (Dama dama),
where pelvic suspension of the carcasses had the greatest impact on meat tenderness in venison from young
male fallow deer (Sims et al., 2004). In addition, previous and recent research has demonstrated quality
differences in meat from ruminants (beef, reindeer (Rangifer tarandus tarandus) and red deer (Cervus
elaphus) that have been grazing pasture or fed grain-based feed mixtures (Daly et al., 1999; Wiklund et al.,
2001a; 2003a; 2003b; Wood et al., 2003; Bruce et al., 2004). However, research in the area of venison
quality has been very limited and further studies of the relationship between production system, slaughter
handling techniques and consumer acceptance of the final products are essential.

Objectives
The objective of this study was to compare the effects of two different techniques for hanging carcasses
(Achilles tendon suspension and pelvic suspension) on the water-holding properties of deer and lamb meat.
In addition, the water holding capacity of long term chilled (up to 6 weeks post slaughter) deer and lamb
meat was measured.

Materials and methods
Ten female lambs (F1 Merino/Border Leicester x Texel, 5½ months old) and 10 female fallow deer (15
months old) raised at the University of Western Sydney, were included in the study. The animals were fasted
for 16 h prior to slaughter, stunned with a captive bolt and bled using thoracic stick exsanguination within 10
s of the stun (ethics approval UWS 04.01). The dressed carcasses were split along the mid ventral axis
approx. 45 – 75 min post slaughter, and each carcass side was randomly assigned to either Achilles tendon
suspension (control treatment) or pelvic suspension. At 1 day post mortem (pm), both M. longissimus
(striploins) from each carcass were collected, cut in 5 pieces and randomly assigned to a treatment of 1, 3 or
6 weeks of refrigerated storage (+2°C), freezing (-20°C) or to be analysed as fresh meat. Drip loss was
measured on the fresh meat samples after hanging meat samples in plastic bags for 2 days at + 2°C. All
other samples were vacuum packaged. Purge (drip loss in the vacuum bags) was measured after 1, 3 and 6
weeks of refrigerated storage by the following procedure: (1) the weight of meat and vacuum bag was
recorded before opening; (2) at opening, any surplus drip on the meat was removed using a paper towel and
the drip-free weight of the meat recorded. Thaw loss was measured using the same technique as described for the purge measurements after the meat samples had been removed from the freezer and thawed overnight at +2°C. Cooking loss was measured for all treatments (fresh, frozen/thawed and chilled-stored meat) after the vacuum packed meat samples had been heated to 70°C in a water bath. The samples were weighed in the same way as described for the purge measurements. The data was analysed statistically by analysis of variance, fitting species for the slaughter data, and species, hanging treatment and their interaction with animal as a blocking factor for the meat quality data, using the statistical package GenStat (2002).

Results and discussion
The lambs had higher live weights compared with the deer (p≤0.01), but lower carcass weights and dressing percentages (p≤0.001) (Table 1). pH decline registered 1-24 hours pm did not differ (p>0.05) between the two carcass treatments or between species (Fig. 1), and the mean ultimate pH values recorded at 24 h pm in M. longissimus (LD) were 5.69 (lamb) and 5.68 (deer). However, after 1 week of refrigerated storage pH dropped below 5.60, and was significantly lower in the lamb than in the deer samples (Table 1). After 3 and 6 weeks of storage pH was not significantly different from ultimate pH (Table 1). These results are in good agreement with an earlier study of red deer meat, where the same pattern for pH variation over storage time was observed (Wiklund et al., 2001b). Mean temperature was higher in lamb than in deer LD at 1 hour (p≤0.05) and lower at 24 hours (p≤0.05) pm, but was not significantly different between species during the main intermediate period of decline.

Among the measured water-holding traits, the carcass suspension technique had an effect on drip loss and purge. Drip loss in fresh meat was significantly lower with Achilles tendon suspension, while purge in the vacuum bags during storage was lower with pelvic suspension, significantly so for 3 weeks storage (Fig. 2). The only significant difference between species was found in drip loss where the deer meat had better water-holding capacity than the lamb meat (1.67% versus 2.24% of drip loss). Cooking loss and freeze/thaw loss was not affected by carcass treatment (p≥0.05), although a significantly higher cooking loss in the deer samples compared with the lamb samples was registered in fresh meat (Fig. 3). The present results on the positive effects of pelvic suspension on purge in deer and lamb support earlier findings in beef (Lundesjö Ahnström et al., 2003), though in the beef study positive effects of pelvic suspension on cooking loss and freeze/thaw loss were also reported. The present values measured for drip loss and cooking loss in lamb samples were in good agreement with previously reported values for lamb LD (Hoffman et al., 2003).

Conclusions
Knowledge about the quality attributes of fresh chilled venison is of strategic importance to the Australian deer industry. Today most of the venison produced is sold frozen, but the demand for fresh meat is expected to increase in the future. Pelvic suspension of carcasses has been demonstrated to improve tenderness in meat from young fallow deer bucks, the type of animals most likely to be supplied for commercial slaughter in Australia. The present results indicate that pelvic suspension also could be positive for water-holding properties of fresh chill-stored fallow deer venison. Pelvic suspension is suggested to be a method that can be used to enhance consumer important quality attributes of venison. Sensory analysis (using a trained expert panel and consumer preference tests) of venison from the two different carcass treatments as well as similar studies on red deer venison are subjects recommended for further investigation.

Acknowledgements
The authors wish to thank Dr Jason Flesch for his professional assistance during slaughter and the collection of samples. Financial support for this work was provided by OECD (Organisation for Economic Co-operation and Development, Paris, France) within the programme “Biological Resource Management for Sustainable Agricultural Systems”.
